Summary

Pain has a profound effect on an animal's wellbeing. In Germany, researchers using animals have been legally required since 1972 to reduce any possible pain, suffering, distress or lasting harm to an absolute minimum. To evaluate how these provisions have been implemented in practice, an assessment of refinements to experimental techniques was conducted by retrospectively reviewing 684 surgical interventions described in 506 animal research applications that were sent to the German competent authorities for approval in 2010. This paper focuses on the efficacy of proposed anesthesia and peri- and postoperative analgesia. Postoperative analgesia was not proposed for 30% of surgeries. Following 10% of procedures, animals were to be given pain relieving medication if the investigators decided this was necessary; however, structured assessments to detect pain were absent. Consequences of unalleviated pain and omission of pain assessment techniques are discussed, and some recommendations to improve anesthesia and analgesia are given. The findings of this review highlight the need for improvement, both to fulfill legal requirements and to improve animal welfare. To monitor compliance with animal welfare regulations, and ensure good veterinary and scientific practices, education and training needs to be intensified. Adherence to the items listed in the PREPARe and ARRIVE guidelines and the Gold Standard Publication checklist (GSPC) should become legally binding.

1 Introduction

Refinement, the last R of the Three Rs principles (replacement, reduction, refinement), was first described by Russell and Burch almost 60 years ago (Russell and Burch, 1959), and pertains to "[m]ethods that minimize any pain, suffering, distress or lasting harm that may be experienced by the animals, and improve animal welfare. Refinement applies to all aspects of animal use, from the housing and husbandry to the scientific procedures performed upon them" (Graham and Prescott, 2015). The revised Directive, 2010/63/EU, requires European Union (EU) Member States to fully implement the Three Rs principles in their national laws (EU, 2010). Most states amended their national legislation in 2013. Well before that, following the revision of the German Animal Welfare Act in 1972, research workers using animals in Germany were required to reduce any possible pain suffering, distress or lasting harm caused to animals to an absolute minimum (Germany, 1972).

Nevertheless, due to limitations in the transparency of the authorization processes and reporting of animal research it has been difficult to assess the extent to which experimental procedures are refined in practice. Structured literature reviews of research that involved the use of laboratory animals have provided some insights. Animal research which involved surgical procedures carried out on species including pigs, sheep, dogs and non-human primates (Coulter et al., 2009), rabbits (Coulter et al., 2011) and rodents (Coulter et al., 2009; Richardson and Flecknell, 2005), published in peer-reviewed journals, has been analyzed, with regard to analgesic and anesthetic administration. Stokes and colleagues (2009) focused on studies conducted in two time periods (2000–2001 and 2005–2006) assessing trends in the administration of analgesics and anesthetics to laboratory mice and rats undergoing surgical procedures. The study showed a trend of improvement regarding safer anesthetic regimens used in the later period examined, but the findings of this and an earlier review assessing analgesic use in rodents (Richardson and Flecknell, 2005) found that there was still significant scope for refinement, especially with respect to perioperative care. Richardson and Flecknell (2005) not only screened the publications for postoperative analgesia but also emailed the authors or their Animal Ethics Committees a survey to verify whether analgesia was administered even though not reported. Response rate was low (28 out of 101 papers); and only 18% of correspondents had given analgesics but not reported it. A systematic review of anesthesia, analgesia and euthanasia methods used in anesthesiology, respiratory and critical care research in the ten highest ranked journals showed insufficient reporting of experimental studies with small laboratory mammals; for example, the administration of analgesics was only
reported in 19% of all painful interventions (Uhlig et al., 2015). An assessment of papers published before 2011 and from 2014 to 2015 further confirmed that reporting of experimental refinement methods is still poor (Carbone and Austin, 2016). Whilst guidance documents especially written for reporting of animal studies, e.g. the Gold Standard Publication Checklist (GSPC) (Hooijmans et al., 2010) and the ARRIVE guidelines (Kilkenny et al., 2010), have been available since 2010, scientific publications still cannot be relied upon to present a detailed description of analgesia and anesthesia protocols. Most recently, reporting of anesthetic and analgesic regimens in publications of studies involving non-human primates once again confirmed the lack of critical detail (Bertrand et al., 2018). Although many journals have adopted guidelines such as “ARRIVE”, publications continue to omit key details of study design and conduct (e.g., Leung et al., 2018). This may be due to a lack of appreciation by researchers for the need to include these data in their publications. It therefore remains unclear to what extent the experimenters did not report on their refinement practices and to what extent, for example, proper pain management was indeed provided. Besides the lack of information regarding refinement in the available publications there is a general lack of transparency within animal research, as in all European Union Member States, access to animal research proposals is generally restricted to members of the regulatory authorities. Thus, the degree to which refinement methods are applied in practice and the awareness of refinement options by research workers remains uncertain.

German animal research proposals stipulate the inclusion of detailed descriptions on how all procedures and interventions would be conducted, including precise descriptions of surgeries and the application of refinements. The most humane and refined methods have to be used while still ensuring valid data collection; this is facilitated by a robust and effective analysis (HBA). For example, if less humane anesthetics are to be used or analgesia is withheld, it must be scientifically justified, and the hoped-for benefits of the research must still outweigh these additional harms. To evaluate the use of experimental refinements in German laboratories, we retrospectively reviewed original animal research applications submitted to the German regulatory authorities for approval in 2010. The efficacy of the proposed anesthetic and peri- and postoperative analgesic regimens, the health monitoring, use of humane endpoints, killing methods and the researchers’ judgement in regard to severity of planned procedures were investigated. The goal was to assess the application of refinements before Directive 2010/63/EU came into effect and to make recommendations about where further improvements could be made. This was the first assessment of its kind. In this paper, we focus on proposed anesthetic and peri- and postoperative analgesic regimens and discuss deficiencies and necessary improvements.

2 Materials and methods

In Germany, reviewing and licensing animal research proposals fall under the authority of each of the federal states. The 16 federal states have their own ‘competent authorities’ for this task, generally comprised of state veterinarians. After negotiations with the highest authorities of the federal states, 14 of the 16 agreed to provide us access to original basic and applied research proposals that had been granted a license. For the scope of our study, we selected all applications, submitted to the participating competent authorities in 2010, that included recovery surgical procedures in mice and rats, to be able to assess appropriateness of anesthesia, perioperative analgesia and postoperative care. We limited the study to the two most commonly used species in Germany: mice and rats. Over 2,000,000 mice and around 400,000 rats per year are used for scientific purposes in Germany (BMEL, 2014, 2017). Elsewhere in Europe, these rodents are also among the most frequently used species (EC, 2013; Home Office, 2017). A total of 506 applications met these criteria and were included in the analysis. They included 684 recovery surgical procedures (422 in mice and 262 in rats).

The study was conducted anonymously (i.e. the individual research groups were not identified in the analysis). Research proposals were included in this study if they met the following criteria:

1. Animal research proposals submitted to German competent authorities in 2010
2. Basic or applied research studies
3. Species: mouse and rat
4. Procedures: surgical, recovery
5. Original proposal that were granted a project license

Research proposals were excluded in this study if they met the following criteria:

1. Applications for the generation of genetically altered mice
2. Government-required animal testing, e.g. toxicity testing of drugs, vaccines, pesticides
3. Species other than mouse and rat
4. Procedures that did not involve recovery surgery
5. Proposals pre-assessed or rejected by members of the competent authorities

We analyzed the experimental protocols based on the original applications. All proposals in this review received a project license. However, before approval of a final license, it is possible and, in some cases, very likely that the competent authorities requested changes to the proposed protocols. To follow up on the results of the competent authorities’ assessments and on their amendments made in the process was not feasible. Also, the scope of our study was to evaluate the researchers’ awareness of and expertise in the application of refinement methods.

Some applications were lacking required information. For example, in a few cases the type, the dose or the route of administration of an anesthetic agent were missing; the justification as to why analgesia was withheld was mostly absent and there was generally no discussion on why certain anesthetic regimes were given preference even when they did not meet the standards of good veterinary practice.

We chose to assess the proposals as originally submitted by the researchers so that we could review the intended use of refinements. This should reflect their knowledge of potential refinements, and also their understanding of the contributions to obtaining high quality research data.

Project licenses were generally granted for up to three years, with the possibility for extension up to five years.
3 Results

3.1 Types of surgical interventions and frequency of endotracheal intubations

The 506 assessed applications comprised 684 surgical procedures as some animals underwent more than one surgery or there were several experimental groups undergoing different surgical procedures. Out of the 684 surgical procedures, 422 were performed on mice and 262 on rats. The most frequently performed surgical procedures on mice and rats were laparotomies, followed by craniotomies in rats. For mice, the second most common surgical procedures were within a general category of all surgeries that did not involve the opening of a body cavity (Fig. 1); examples include neuropathic pain models such as compression or ligation of nerves (e.g., ischiatic nerve), implantation of catheters in veins and arteries (e.g., femoral artery or vein, jugular vein), hindlimb ischemia model (by ligation of the femoral artery), or the middle cerebral artery occlusion (MCAO) model to cause focal cerebral ischemia. Endotracheal intubation was planned to be performed for 15% of surgeries, the vast majority (82%) being thoracotomies in mice, and for 8% of surgeries on rats with over half of these being for thoracotomies.

3.2 Anesthetic regimens and agents used

Injectable anesthetics were the most commonly used anesthetics in procedures on both mice (55%) and rats (48%), followed by volatile agents (mice: 36%; rats: 38%) (Fig. 2). A combination of injectable and inhalational agents was used in about 10% of surgeries (Fig. 2). In 1% of surgeries the investigator did not provide information on anesthesia. For another 1% of the surgical interventions it was not planned to use an anesthetic agent. Instead the investigators intended to use hypothermia (cooling the animals to 1–4 degrees Celsius by laying them on ice for about six minutes to immobilize them) to immobilize neonatal mice and rats while carrying out intracranial injections with virions or neuroblasts.

3.2.1 Injectable agents used for anesthesia

Ketamine and xylazine were the most frequently used injectable anesthetic combination in mice (79%) and in rats (70%). A completely reversible anesthetic regimen, a mixture of fentanyl, medetomidine and midazolam, was used in 11% of mice and in 5% of rats. Choral hydrate was the second most frequently used agent in rats (6%) but was rarely administered to mice (<1% of procedures). Ketamine and medetomidine were found to be used more frequently in rats (6%) than in mice (2%). Pentobarbital use ranked between 3% in mice and 5% in rats. Other single agents for mice were medetomidine (1%) and
ketamine (<1 %). Acepromazine was combined with xylazine and ketamine for rats (5 %). In mice, acepromazine was combined with ketamine but was used rarely (< 1 %). The mixture of fentanyl, flunisone and midazolam was exceptionally used for mouse and rat surgeries (2 %). In a few cases it was stated that reversible anesthetic agents would be antagonized at the end of the procedure.

3.2.2 Inhalational agents
Isoflurane was by far the most widely used inhalation agent (74 % and 70 % of procedures performed on mice and rats, respectively), followed by the combination of isoflurane and nitrous oxide in both species (15 %). For surgeries on mice, nitrous oxide was also used in combination with halothane (9 %) as well as halothane alone (1 %) whereas for rat surgical interventions, no halothane use was reported, but sevoflurane (8 %) and methoxyflurane (7 %) were used.

3.2.3 Combination of inhalational and injectable anesthetics
The combination of inhalational agents with injectable anesthetics or sedatives was used in 9 % of surgeries on mice and 13 % of surgical intervention on rats. Here the most frequently administered injectable agents – ketamine and xylazine – were combined with the most widely used volatile anesthetic isoflurane: 39 % for mice; 56 % for rats. The next most commonly used combination of anesthetics for mice was isoflurane and ketamine/midazolam and for rats isoflurane/nitrous oxide with ketamine/xylazine. In the majority (61 %) of cases anesthetic induction was performed with the injectable anesthetics/sedatives, followed by the use of volatile agents. In some exceptional cases in rats, ether or carbon dioxide was used to initiate anesthesia. Carbon dioxide was however frequently used for killing animals (Herrmann and Flecknell, 2018).

3.3 Perioperative analgesia
The most frequently used perioperative analgesic agent for both mice and rats was buprenorphine (mice: 38 %; rats: 31 %), followed by carprofen (mice: 29 %; rats 27 %) and fentanyl (mice: 12 %; rats: 7 %) (Fig. 3). Local anesthetics such as lidocaine, xylocaine, ropivacaine, bupivacaine and amethocaine were used in 10-13 % of procedures. For instance, 22 % of the craniotomies and 10% of the thoracotomies involved the application of local anesthetics at the surgical site. Metamizole was used in 8-9 % of cases, followed by other analgesics such as paracetamol, flunixin meglumine and butorphanol. Tramadol was used rarely in mice, but was administered after 8 % of surgeries on rats. Meloxicam was the least often administered agent in both species (Fig. 3).

When analgesics with no or minimal analgesic properties were used it was assessed whether and when they were combined with analgesics. In the case of isoflurane, 25 % of mice and 28 % of rats received no pain relief, and 13 % of mice and 18 % of rats received pain relief at the end of surgery (Fig. 4).

When injectable agents with no specific analgesic activity such as pentobarbital or chloral hydrate were used we reviewed if these were combined with analgesics: With pentobarbital analgesia was not provided in 55 % of surgical procedures on mice and in 75 % of surgical procedures on rats. Chloral hydrate, an injectable anesthetic that was most frequently used for craniotomies in rats, was most often combined with tramadol given intraoperatively and, less often, with a local anesthetic.

![Fig. 3: Percentage of analgesia agents and local anesthetics used perioperatively for mice and rats](image1)

Local anesthetics used were lidocaine, xylocaine, ropivacaine, bupivacaine and amethocaine. “Other” agents used included paracetamol (acetaminophen), flunixin meglumine and butorphanol.

![Fig. 4: Time of analgesic administration when isoflurane was used](image2)

74% and 70% of surgical interventions, in mice and rats respectively, of all inhalational anesthetic regimens used isoflurane.
3.4 Postoperative analgesia

Postoperative analgesia was administered following 57% of the surgical interventions on mice, less than 1% being multimodal, and 62% of procedures on rats, including under 2% of multimodal analgesic regimens (Fig. 5).

Fig. 5: Decision on administration of analgesic following surgical interventions (422 on mice and 262 on rats respectively): yes, no, and “if needed” according to the opinion of the researcher.

</table>
The surgical procedures where multimodal analgesia was provided postoperatively are listed in Table 1 (for mice) and 2 (for rats). In one of the two mouse procedures, the multimodal approach was optional, depending on pain being detected. The first three postsurgical regimens in Table 2 are identical and were used after various surgical procedures all described in the same research application. One of the aortic banding surgeries, a commonly used experimental model for pressure overload-induced cardiac hypertrophy and heart failure, used the multimodal approach only in case the animals would not drink enough as metamizole was supplied via the drinking water and/or they showed signs of pain. The two applications with aortic banding (Tab. 2) represent two of the very few that mentioned they would observe water intake. One application stated on the amount that the rats were expected to drink from 8 weeks old (8-12 ml/kg body weight).

No postoperative analgesia was given after 32 % of mouse surgeries and after 30 % of rat surgeries (Fig. 5). Reasons for withholding analgesia were given in 24 % of surgeries on mice and in 33 % of surgical procedures on rats. The most frequent explanations were that it was not seen as necessary as pain was anticipated to be minor, and that the analgesic agent could influence study outcomes. In 11 % of surgical procedures on mice and in 8 % of surgical procedures on rats the investigators declared that they would administer analgesia only “if needed” (Fig. 5). Pain management would be considered “when signs of pain and/or suffering were observed” or “in case of signs of moderate pain”. Some stated that, according to their experience, analgesia was not necessary for the planned surgical interventions and that the surgery was “tolerated well by the animals”. Overall, there was no account in these applications that a structured pain assessment would be conducted.

The general health score sheets that a small number of proposals had attached (13%), focused on various health indicators, including humane endpoints, most of them not being specific for pain (article in preparation).

Similar to the intraoperative pain management for mice and rats, buprenorphine (mice: 33%; rats: 34%) and carprofen (both: 33%) were the most utilized agents to manage postoperative pain, followed by metamizole (mice: 20%; rats: 13%) (Fig. 6). Tramadol was used postoperatively in 10 % of surgeries in rats but only in 3 % of surgeries in mice. Meloxicam was more popular after interventions in mice (4 %) than in rats (2 %). Other rarely used agents were paracetamol, acetylsalicylic acid, flunixin meglumine and local anesthetics (Fig. 6).

Information regarding duration and frequency of postoperative analgesic application was incomplete. When indicated, buprenorphine was often given between one and three times a day subcutaneously (s.c.). Durations varied between one to three days and longer. Some administered buprenorphine intraperitoneally (i.p.) or intramuscularly (i.m.). Carprofen was given mostly s.c., but at times i.p., i.m., orally or via the drinking water. When not given via the drinking water, it was administered once or twice daily, and duration of administration varied from one to three day, or occasionally longer. Metamizole, paracetamol, tramadol and acetylsalicylic acid were usually given via the drinking water. Duration of administration of metamizole varied between one to five days, in some cases up to seven days and longer. Paracetamol was given most frequently for two to three days. For tramadol, the duration was rarely mentioned and for acetylic acid not at all. The local anesthetics route of administration was mostly not specified.

Analgesic doses given were usually within the standard published ranges with the occasional low, for example 2.5 mg/kg of carprofen in rats, or high, 30 mg/kg of carprofen in mice. Meloxicam was dosed mostly at 0.2 mg/kg. Dosages for metamizole supplied via the drinking water ranged between 1.3 mg/ml and 2.5 mg/ml. Other doses noted were 110 mg/kg, 200 mg/kg and 300 mg/kg. Paracetamol was given at 1-3 mg/ml drinking water. Tramadol drinking water dosages were 30 to 50 mg/kg/8h or 25 mg/L up to 200 mg/L drinking water. It was rarely reported whether the drinking water intake would be measured, and how much an animal, according to their body weight, was expected to drink to assure sufficient drug levels. A few investigators stated that they would administer the analgesic s.c. if animals showed pain despite having the agent in their drinking water. In one proposal, administration of tramadol via the drinking water was started preoperatively. A small number of investigators stated that they would switch to another analgesic agent or give an additional analgesic if pain was not controlled effectively. Some asserted that they would provide analgesia until no more pain was observed. Information in regard to structured pain assessments was absent. A small part of proposals included health score sheets, and their quality varied. The vast majority monitored general indicators for deteriorating health not specific to pain—such as weight loss, alterations in body temperature and tumor size. When declaring that the animal’s behavior and overall health condition would be monitored it was mostly unclear to what extent this would be done and what would be done to alleviate clinical signs (analgesia; special bedding or other measures of intensive care). The planned frequency of monitoring of the animals was
mentioned for about 33% of all surgical intervention, and in the majority of cases these checks were to be done once a day. More results on health monitoring, severity of procedures and assessment outcomes in regard to the humanness of study endpoints and killing methods will be published elsewhere.

4 Discussion

We found shortcomings in all areas we assessed. First and foremost, pain was not alleviated or was unlikely to be alleviated effectively. Following 30% of surgical interventions no analgesia was provided at all, and in another 10% of procedures it would be alleviated if pain was observed. However, monitoring seemed to generally lack. Reasons for withholding analgesia, if included, highlighted not only a general lack of monitoring, a lack of pain assessment and a lack of pain recognition skills. It also showed that concerns about the negative effects of analgesics on study outcomes were greater than the concerns about untreated pain. Considering the severity of planned surgical interventions, it was unexpected that use of multimodal analgesia was almost non-existent. Furthermore, preventive analgesia was often not provided when, for example, an anesthetic was used which had no analgesic properties (e.g., isoflurane); this was the case in a quarter of these procedures, and in another 13-18%, it was given too late, and thus, the animals would recover consciousness without pain relief. Moreover, the use of local anesthetics for severe surgeries such as thoracotomies was very low (10% of thoracotomies). In the following, we discuss the problems we identified in detail and provide some information as to how these could be improved or resolved. We consider implementation of these refinements would both significantly improve animal welfare and improve the quality of data obtained.

4.1 Unalleviated pain

Due to the absence or the inadequacy of pain management during and after surgery in our study, we commence the discussion with general consideration on the effects of unalleviated pain. Research workers are often concerned that (side)effects produced by analgesics (and anesthetics) could potentially influence or even confound study outcomes and data. However, there is an abundance of information on the pharmacodynamics, pharmacokinetics, unwanted effects, toxicity and interactions with other drugs2 (e.g., Flecknell, 2016; Gaynor and Muir, 2014; Grimm et al., 2015; Informationssystem CliniPharm CliniTox, 2018; Muir and Hubbell, 2014) to guide investigators when designing their studies. In addition, there is an increasing number of recommendations for the refinement of certain models and procedures, for example, for mice and rats who are utilized as models of ischemic stroke (Perce du Sert et al., 2017), for rheumatoid arthritis (Hawkins et al., 2015), for sepsis and septic shock (Lilley et al., 2015), for experimental autoimmune encephalomyelitis (EAE) (Wolfensohn, 2013a), and for procedures involving seizures, convulsions and epilepsy (Wolfensohn, 2013b; Lidster et al., 2016). These guidelines were composed by experts based on their knowledge of the particular models and the value of potential refinements. In addition, specialists in veterinary anesthesia and analgesia in a research setting can give additional, project-specific advice and guidance.

Unalleviated pain has profound effects on the animal leading to emotional, behavioral and physiological changes (see Jirkof, 2017; Peterson et al., 2017). The immune system is suppressed due to pain stimulating glucocorticoid and catecholamine release. Responses to pain vary between individuals, and consequently are hard to predict, which makes pain a potentially poorly controlled study variable. In comparison, the influence of anesthetic and analgesic agents on the data is more foreseeable than the effects of unalleviated pain, distress and suffering on in vivo research. In addition, use of perioperative analgesics - if based on the need of the individual animal elicited by properly and frequently conducted pain assessments - will most likely have relatively minor effects on the animal model. Confounding effects are more likely to be introduced by analgesics when the agents are given over an extended period or in unnecessarily high dosages. The likely effects are often overestimated and based on studies in which analgesics were administered at elevated dose rates and for time periods longer than needed in most experimental settings (e.g., Hall et al., 1996). Furthermore, models designed to be of relevance to clinical conditions in humans should be treated as in the human setting where pain would generally be alleviated whenever possible. A plan for adequate and controlled pain management should be developed as part of the study protocol. To sufficiently manage pain, the choice of anesthetics and analgesics, their dose, administration route, frequency and duration of treatment, and a pain assessment plan should be tailored to the individual research project, treatment group and, if necessary, to an individual animal’s needs.

4.2 Need for refinement of anesthetic protocols

Endotracheal intubation

Intubation was performed in 8% and 15% of surgeries (rats and mice respectively), and the majority of these were thoracotomies. When opening the thoracic cavity, endotracheal intubation is generally indicated as the animals require mechanical ventilation to maintain respiratory function. In addition, there are certain disease models where intubation and mechanical ventilation is of considerable benefit. For example, the lesion size in experimental models of stroke is influenced by cerebral blood flow and the degree of cerebral vasodilation, and these variables are markedly affected by changes in arterial carbon dioxide. This can be stabilized and maintained at a consistent level by mechanical ventilation (Liu et al., 2009). Tracheal intubation might appear challenging in small rodents but it is relatively easy to perform with the correct apparatus (Flecknell, 2016).

Hypothermia

For experiments where neonatal mice and rats were injected intracranially, the researchers planned to use hypothermia to immobilize them. The investigators would then inject the animals’ brains with virions or neuroblasts. In neonatal rodents, the nociceptive pathways are thought to be not yet fully developed (Fitzgerald, 2005). However, recovery from hypothermia is possibly associated with pain as it has been shown to lead to c-Fos activation (Rhodes, 2009). Since there are much safer and likely more humane anesthetic agents available for neonatal mice and rats such as methoxyflurane (Dunneman and Mandrell, 1997) or fentanyl/fluanisone (Clovery and Flecknell, 2000) the use of hypothermia should be abandoned. It is our understanding that the German competent authorities generally do not allow this controversial practice (Projektgruppe der Genehmigungsbehörden, personal communications, 2016).

Pentobarbital
A number of surgical interventions were conducted under the hypnotic agent pentobarbital which was given intraperitoneally. Doses ranged from 36 mg/kg body weight up to 60 mg/kg in mice and up to 70 mg/kg in rats whereas recommended doses are between 40-50 mg/kg (Field et al., 1993). Pentobarbital has a narrow safety margin is best used for providing a light plane of anesthesia rather than for surgical interventions, when dose rates close to the lethal dose may be required (Flecknell, 2016). The high pH of pentobarbital (11) causes pain when injected intraperitoneally. Pentobarbital also results in prolonged sleep time in rats (120-240 minutes) and mice (120-180 minutes) (Flecknell, 2016), and during this period, animals remain with depressed cardiovascular and respiratory systems and are susceptible to hypothermia.

Chloral hydrate
Chloral hydrate was rarely used in mice, but was the second most frequently used agent in rats. However, it can cause adynamic ileus in rats (Fleischman et al. 1977). It often produces only a light plane of anesthesia; most investigators planned to give perioperative analgesia. Nonetheless, due to the danger of causing ileus chloral hydrate should be replaced by more effective and safer agents (Baxter et al., 2009).

Use of ketamine or medetomidine as the sole agent
There were few cases were the use of ketamine or medetomidine as single agents was planned. Used alone these agents cause sedation and mild to moderate analgesia but must be combined with other agents to produce surgical anesthesia; the combinations of ketamine with acepromazine or ketamine with midazolam do not usually provide an anesthetic depth necessary for surgery in both species (Flecknell, 2016); hence, when used for surgical interventions additional agents are needed.

Use of inappropriate inhalational agents for induction of anesthesia
For rats, ether was used in 3% and carbon dioxide in 6% of protocols to initiate anesthesia. Induction with both of these agents is distressing and aversive due to the irritation of the mucus membranes. Coughing, salivation and at times laryngospasm occur from inhaling ether (Flecknell, 2016). Carbon dioxide is strongly aversive, and causes distress and fear in rodents (e.g., Chisholm et al., 2013; Kirkden et al., 2008; Leach et al., 2002a, 2002b, 2004; Makowska and Weary, 2009; Marquardt, 2013; Niel and Weary, 2007; Niel et al., 2008; Wong et al., 2013; Ziemann et al., 2009) and thus, its use as a killing agent has been controversial for many years. Rats and mice are unwilling to tolerate exposure to CO₂ long enough to lose consciousness (Leach et al., 2002b, 2004; Niel and Weary, 2007; Niel et al., 2008). Food incentives to stay in the gas chamber (Leach et al., 2004; Niel and Weary, 2007) and withholding food for up to 24 hours to increase their motivation to stay in the chamber longer as well as varying the gas flow rates did not change the time they were willing to tolerate the carbon dioxide (Niel et al., 2008). When comparing carbon dioxide to other anesthetic gases, it was found to be the most aversive gas for both mice and rats, with the least aversive being enflurane and halothane for mice and halothane for rats (Leach et al., 2002a). Other studies compared rats’ aversion to carbon dioxide with isoflurane or halothane exposure and concluded that the fluorinated hydrocarbons were less aversive than carbon dioxide (Kirkden et al., 2008; Makowska and Weary, 2009; Wong et al., 2013; Young, 2006).

Recommendations
Dosing and route of administration
Drug doses vary between species, strains and individuals and depend on age, sex and health condition of the individual animal (Flecknell, 2016). Therefore, we only discuss chosen dosages if they were outside of the standard range. Injectable anesthetics were the most widely used agents in both mice and rats. They can provide safe and effective anesthesia, but this is most easily achieved when given intravenously, so that the dosage can be adjusted to provide the desired effect in that particular animal. However, this is generally not feasible for small rodents who thus receive most injectable anesthetic agents intraperitoneally (i.p.) and less often subcutaneously (s.c.) or intramuscularly (i.m.). Several studies have shown that intraperitoneal applications have a high failure rate (6-20 % for experienced personnel) with some of the material being injected, e.g., in the fatty tissues, viscera or caecum (Ballard, 2009; Coria-Avila et al., 2007; Gaines Das and North, 2007; Lewis et al., 1966). Intramuscular injections can be painful, and in the case of ketamine, for example, they can produce necrosis (Smiler et al., 1990). The subcutaneous route seems the least invasive, however, data comparing the accuracy of dosing with i.p. administration is not available. Since injectable anesthetics are administered as a single dose, overdosing or underdosing can easily occur. To avoid complications, agents with a wide safety margin should be used as well as agents whose effects can be reversed using specific antagonists.

Reversible anesthetic agents
Due to their small body size, rodents are prone to hypothermia, and respiratory and cardiovascular depression, and mortality increases with prolonged postsurgical sleep time. This risk can be reduced by using anesthetic agents that can be reversed
such as medetomidine and xylazine with atipamezole; midazolam with flumazenil and fentanyl with butorphanol, buprenorphine or naloxone. Some, but far from all, researchers who used reversible anesthetic regimens planned to anticipate these at the end of the procedure. This should be done routinely to avoid long sleep times and ensure a faster recovery. Fleischmann et al. (2016) demonstrated in their recent study that without the use of antagonists, mice showed pronounced hypothermia and bradycardia for several hours. Most investigators in our study sample used ketamine and xylazine, a regimen associated with prolonged recovery periods (Albrecht et al., 2014). Ketamine/xylazine and ketamine/medetomidine could be partially antagonized with atipamezole; this should be considered to reduce recovery time.

**Pre-medication and balanced anesthesia**

Isoflurane was the most frequent inhalational anesthetic used. There seems to be a general trend towards using volatiles, probably because induction is rapid, anesthetic levels can be adjusted to the individual animal’s needs, and recovery from anesthesia is fast. Isoflurane undergoes almost no biotransformation; however, it is mildly pungent (Eger, 1981). Most commonly used inhalational agents are to some degree pungent to rodents, and studies have shown increased aversion and distress after repeated exposure to e.g., isoflurane and halothane (Makowska and Weary, 2009). Hence, it is advisable to use pre-medication such as fentanyl/fluanisone or midazolam/fentanyl for induction before maintenance with an inhalational agent. Other commonly used pre-medication agents are medetomidine, dexmedetomidine or xylazine. Another advantage of using sedatives and analgesics as pre-anesthetic medication is that it produces a balanced anesthesia where the dosage of each component can be reduced, while inducing general anesthesia of sufficient depth with fewer side effects. For example, administration with midazolam and fentanyl has been shown to improve sevoflurane anesthesia for moderately painful surgeries in mice (Lipski et al., 2017). Depressant effects of sevoflurane on respiratory rate and the negative post-anesthetic effects on heart rate were decreased due to use of pre-anesthetic medication. Hence, to avoid unnecessary animal distress as well as to minimize potential negative effects of anesthesia on the research subject balanced anesthesia should be the norm.

### 4.3 Inadequate analgesia

**Lack of preventive analgesia**

When anesthetics with no or minimal analgesic properties were used, for example, in the case of isoflurane, 25% of mice and 28% of rats received no pain relief, and 13% of mice and 18% of rats received pain relief at the end of surgery. Anesthetic agents without analgesic properties such as isoflurane and sevoflurane should always be combined with analgesics to ensure sufficient pain relief at the time the animal regains consciousness (Flecknell, 2016; Miller and Richardson, 2011). Since most analgesics only reach full onset of action 15 to 45 minutes after administration, it is advisable to administer the analgesic preoperatively. Preventive analgesia reduces both noxious stimuli reaching the central nervous system during surgery and peripheral inflammation (Miller and Richardson, 2011). Perioperative analgesics may also have an anesthetic sparing effect (Penderis and Franklin, 2005).

**Lack of local anesthetics use**

Splash blocks (instillation of local anesthetics at surgery site) were used in 22% of the thoracotomies local anesthetics were used for intercostal infiltration or as splash blocks. To incorporate local anesthetics into intraoperative regimens of surgeries known to cause severe pain would be a valuable refinement. Combining lidocaine (10mg/kg) and bupivacaine (5mg/kg) provides safe and effective analgesia in a range of species (Flecknell, 2018).

**Absence of multimodal analgesia**

Multimodal analgesia, the use of different classes of analgesics, including local anesthetics, opioids, and NSAIDs in combination, represents current best practice. Besides this approach being the most effective in managing pain it also helps to avoid side effects caused by the use of high doses of a single analgesic agent (Miller and Richardson, 2011; Flecknell, 2016). In our review, multimodal analgesia was rarely chosen, and the regimens reported should be refined further for reasons discussed in this section.

**Intake via the drinking water**

The sole application of an analgesic agent in the drinking water was a frequent method of analgesic administration, but effectiveness of this approach for managing pain is highly questionable as it is uncertain if the individual animals consumed sufficient analgesic to reach effective plasma concentrations (Sauer et al., 2016). This is especially difficult to achieve during the light phase of the animal’s photoperiod when mice and rats drink infrequently (Graf et al., 2016). An additional problem can be the unfamiliar taste of the medicated drinking water. To accustom the animals to the water mix, provision should start a day or two before the surgical intervention (as proposed by one of the investigators in our study). A recent study demonstrated that the mixture of tramadol and paracetamol was voluntarily consumed via the drinking water in sufficient amounts to alleviate mild to moderate postsurgical pain (Jirkof et al., 2018). It was concluded that this protocol should at least partially alleviate pain, but the authors considered that additional analgesic agents would be required after surgical interventions that caused more severe pain. Analgesic delivery via the drinking water should be combined with another analgesic, given by injection to provide analgesia during the light phase of the animal’s photoperiod when water intake is decreased (Sauer et al., 2016). It is also practicable to train animals to consume analgesics in a palatable base, and to dose animals individually in this way (Kalliokoski et al., 2011; Leach at al., 2010).

Studies of the efficacy of the oral application of metamizole, an agent that seems especially popular in German laboratories (see Fig. 3and 6), appear not to have not been conducted. Metamizole is one of the non-acidic antipyretic analogesics and a pyrazolone derivate with antipyretic and analgesic properties. It’s use in medical practice was prohibited in many countries since the 1970s after its use was linked to agranulocytosis. However, it appears that the risk of metamizole-
induced agranulocytosis was exaggerated (Jasiecka et al., 2014) and the agent continues to be available in Germany. A study to verify the efficacy of this agent is urgently needed to determine if it is an effective postoperative analgesic in rodents.

**Analgesic dosing**

Analgesic doses administered should be selected according to the anticipated and then actual severity of the surgical intervention, the strain and the animal’s individual response to the treatment (Wright-Williams et al., 2013). The general dose recommendations for carprofen given to mice are 4-5 mg/kg (e.g., GV-SOLAS and TVT, 2015) and for ketoprofen 2-5 mg/kg (Matsumiya, 2012). Depending on the degree of acute pain, a 2- to 4-fold higher dose would be needed for the analgesic to be efficient (Matsumiya, 2012). However, these increased dose rates of NSAIDs may result in undesirable side effects such as gastrointestinal ulceration.

Meloxicam, at the dose rates proposed, is unlikely to be effective in managing postoperative pain since significantly higher dose rates are required (Roughan et al., 2016; Wright-Williams et al., 2007). A recent re-assessment of the efficacy of meloxicam for post-laparotomy pain in mice suggested that it had anti-inflammatory activity, but it failed to prevent pain, even at high dose rates (Roughan et al., 2016). A slow-release formulation of meloxicam also showed inability to control pain of rats after skin incision under general anesthesia (Seymour et al., 2016).

**Slow release formulations**

Repeated handling and restraint cause distress (Balcombe et al., 2004; Meijer et al., 2006) and can add to postsurgical pain in newly operated animals (Jirkof et al., 2015). Thus, the frequency of analgesic injections should be minimized. However, the serum concentration for buprenorphine (Temgesic®), for instance, indicates that the duration of action in mice is less than 8 hours (Jirkof et al., 2015). Thus, to maintain effective serum concentrations this agent should be given at approximately 6 hourly intervals. Slow-release formulations could be administered to reduce this to once every 24-48 hours in mice (Jirkof et al., 2015; Kendall, 2016) and up to once every 72 hours in rats (Foley et al., 2011; Chum, 2014). However, these slow-release formulations are currently only available in the USA.

**Non-provision of analgesia: reasons, responsibilities and refinement**

No postoperative analgesia was planned to be given after approximately 30% of mouse and rat surgeries respectively. Since all assessed procedures were surgical procedures occurrence of pain was to be expected. Annex VIII of Directive 2010/63/EU (similar to previous guidance documents on severity of procedures) classifies “surgery under general anesthesia and appropriate analgesia, associated with post-surgical pain, suffering or impairment of general condition” as moderate in severity and “surgical and other interventions in animals under general anesthesia which are expected to result in severe or persistent moderate postoperative pain, suffering or distress or severe and persistent impairment of the general condition of the animals” as severe (EU, 2010). By contrast, over half of the 684 surgeries included in our review were classified as mild by the researchers (Herrmann and Flecknell, in print). Explanations for not expecting and not detecting pain might be due to the overall low frequency of observations of the animals and the absence of structured pain assessments as well as in a general lack of knowledge about pain-related behaviors in mice and rats and the impact/severity of surgical interventions performed on them.

Ensuring that the animals used in procedures experience the minimum of pain, distress and suffering is one of an investigator’s primary responsibilities. Research applications planning to not provide postoperative pain management, with no scientifically plausible explanation should not be approved. If withholding pain relief is indeed necessary from a scientific standpoint the harm-benefit analysis has to demonstrate that the anticipated benefit of the research outweighs and thus justifies the painful experience for the animal. When analyzing the restrictions of research studies in detail, a solution/compromise can often be found. It might not be possible to provide the animal with the best available pain management, but it is almost always possible to improve the animal’s welfare, at least by preventing factors that can cause and increase pain and distress. Appropriate peri- and postoperative measures also help the animals to recover more rapidly.

Postoperative pain is likely to be present at least 48h following surgery, and longer when more invasive procedures such as thoracotomy or orthopedic procedures are undertaken. Since all opioids that are currently available in the EU have a duration of action of less than 8h, repeated administration will be required to provide effective analgesia. When used alone, particularly in mice, NSAIDs provide insufficient analgesia following major surgery. Although handling and restraint to administer additional analgesics can cause stress, prior positive reinforcement training of the animals, and use of tunnel handling of mice, can greatly reduce this adverse effect. In any event, the stress of handling is likely to be minimal in comparison to unalleviated post-surgical pain.

**4.4 Lack of recognition and assessment of pain**

After 10% of all surgical procedures the researchers stated that analgesia would not be necessary, but would be provided if signs of pain or suffering were observed. As mentioned before, information concerning structured pain assessment was generally absent. Our findings correlate with results from a study conducted in the UK where almost none of the 28 institutions in the survey used pain assessment methods. Although their efficacy was not assessed, the British laboratories provided the animals with analgesics as a routine (Hawkins, 2002).

In many cases, investigators assured animals would be monitored “frequently” without defining what this would mean. When the frequency of health inspections was specified, most of these checks were to be done once a day. Yet, daily inspections are a minimum legal requirement for healthy animals (E.C., 2007). Even before Directive 2010/63/EU was published, recovery surgical procedures were generally rated as at least moderate in severity (Martini et al., 2000). Thus, animals that have undergone surgery require much more frequent monitoring to assure that pain is recognized and managed effectively.
Recommendations

Positive reinforcement training

The degree to which pain is perceived and the way the presence of pain is expressed by animals varies greatly between species, strains, sexes, age, health status as well as among individuals. In the light of this, the importance of implementing proper pain assessment schemes becomes apparent as it is not sufficient to administer an analgesic and assume that pain is alleviated. Observations to assess pain are more likely to be successful when animals are familiar with the people who observe and handle them and provide veterinary care. This highlights the importance of frequent positive interactions with the animals. Besides gentle handling practices (Hurst and West, 2010; Gouveia and Hurst, 2013) successes of positive reinforcement training in mice (Leidinger, 2018) and rats (Schuppli et al., 2017) show that positive animal-human relationships help with assuring their pain is managed effectively.

Monitoring criteria

Common behavioral alterations in mice and rats that can indicate pain are for example, decreased activity levels (Wright-Williams et al., 2007; Karas, 2002), sleep disturbances, reduced water and food intake (Liles et al., 1993; Carstens et al., 2000), changes in nest building (Deacon, 2012; Jirkof et al., 2013; Jirkof, 2014), burrowing (Deacon, 2006, 2009, 2012; Jirkof et al., 2010; Jirkof, 2014), and grooming behavior (Miller et al., 2016). Specific behaviors associated with abdominal pain in rodents include pressing the abdomen against the cage floor, raising the tail while walking, frowning, twitching of back muscles, partial loss of balance when walking and lifting one leg straight out behind (Wright-Williams et al., 2007; Leach et al., 2012; Miller et al., 2012, 2016). The observation and scoring of these behaviors can be complemented with monitoring of burrowing and nest building behaviors as in some strains these have been shown to be useful not only for disease progression, but also as signs of pain and distress (Jirkof, 2014). A prerequisite is that for the particular strain baseline data is obtained.

Another approach to pain assessment is the use of the grimace scale for mice (Langford et al., 2010; Leach et al., 2012) and rats (Sotocinal et al., 2011). The Mouse Grimace Scale (MGS) and Rat Grimace Scale (RGS) have been used successfully to assess spontaneous, postoperative pain that can be detected for 36 to 48 hours after surgery (Matsumiya, 2012). For research purposes the MGS and RGS are used by scoring images taken from digital video, the system can also be used at cage side by animal care staff and research workers (Matsumiya, 2012), who confirmed user friendliness and sensitivity of the method (e.g., Faller et al., 2015). Using multiple blind observers, previously overlooked low-level pain was identified in a study where the system was used to assess the efficacy of the post-surgical analgesia protocols following thoracotomy for surgical induction of myocardial infarction (Faller et al., 2015). Furthermore, this tool has shown potential in the search for effective analgesic dose ranges. The use of the MGS showed that currently recommended dosages of carprofen and ketoprofen were insufficient in managing postsurgical pain, and that paracetamol was an inadequate agent at any dose (Matsumiya et al., 2012). The grimace scale should be combined with monitoring other pain-related behaviors mentioned earlier, water and food intake, locomotor and exploratory activity as well as changes in nest building and burrowing behavior, in order to optimize pain management strategies. Structured pain assessments take time and therefore require trained personnel in sufficient numbers. However, they are central to assuring the efficacy of analgesic treatment.

Monitoring in the nocturnal phase

Rodents are generally more active in the dark phase of their photoperiod (Wells, 2017), so other useful tools to employ are remote video-monitoring of animals in their home cage and, in certain settings, the use of automated cages whose systems are able to detect and record rapid changes in normal behavior (Miller et al., 2011; Wright-Williams et al., 2013; Lourdau et al., 2001). Limitations of currently available automated cages are that abnormal behaviors that are associated with pain such as pressing the abdomen on the cage floor or slow contraction of abdominal flank muscles are not detected.

5 Conclusions

The findings of this first-of-its kind review of original animal research proposals confirm international trends detected in the various appraisals of the literature (also see Bara and Joffe, 2014; Taylor, 2010; Pound and Nicol, 2018; Uhlig et al., 2015). Although reporting of analgesia and anesthesia in scientific publications is often incomplete, it is highly probable that, for example, postoperative analgesia had not been provided when it was not mentioned in the publication. Our assessment showed that legal requirements to comprehensively apply available methods of refinement were not followed. In particular, pain management was either not planned to be provided or the proposed regimens were not appropriate, and optimal techniques such as multimodal analgesia were almost never used to alleviate postoperative pain in laboratory rodents. Pain assessment tools and schemes were not utilized, and effective health monitoring seemed to be lacking. To assess whether the situation has changed since Directive 2010/63/EU came into effect in 2013, it would be important for this study to be repeated, as well as expanded to other EU Member States.

Since animal research workers are legally bound to alleviate discomfort, pain and suffering to an absolute minimum, a possible explanation for the deficiencies in the research applications is that they have not received sufficient education as well as adequate on-going training in refinement methods and animal welfare. The many investigators who underestimated the severity of their procedures also suggests there is a knowledge gap. To ensure that animal research is conducted in the most responsible and least invasive way resulting in findings that are valid and reproducible, professional assistance and comprehensive training are required. It is important to explain to researchers not only how experiments, husbandry and care could be refined, but also why this is central to producing high quality research data. To adhere to all the Three Rs, specialists in reduction and in replacement and alternative, animal-free approaches should also be consulted during study planning. Every research institution should ensure that these experts are available to advise and assist research workers.
when planning, designing, conducting and reporting their studies; and if a research institution does not have such expertise, outside specialists should be sought. Education and training have been one of the focus areas of the new Directive, and a guidance document to improve and harmonize education and training in the EU was produced by an Expert Working Group (National Competent Authorities, 2014). Incorporating the learning outcomes into the relevant training modules, and ensuring that all new research workers attend formal courses to deliver this training effectively should improve the implementation of refinements. Refresher training for more experienced researchers has been recommended and more formal requirements for this should also be considered.

It is critical that clear descriptions regarding the provision of adequate pain management (and all other refinements) are included in research proposals as well as in publications to avoid needless pain and suffering of the research subjects. Full disclosure is also essential to enable the replication of the studies and to understand the findings. Researchers build their work on the work of other researchers, mostly by using information given in publications, and regulatory authorities and bodies, such as animal research and ethics committees, Animal Welfare Bodies (AWBs) and Animal Care and Use Committees (ACUCs), make their decisions on the content presented in proposals. Hence, openness about all aspects and details is imperative.

Finally, investigators should closely follow the PREPARE (Smith et al., 2017) and ARRIVE guidelines or the Gold Standard Publication Checklist (GSPC) to provide essential data required for interpretation of their results. Funding agencies and scientific journals still do not demand full disclosure of this information (Baker et al., 2014; Carbone and Austin, 2016; Enserrink, 2017; Reichlin et al., 2016). A recent randomized controlled trial of an Intervention to Improve Compliance with the ARRIVE guidelines revealed that the request to fill in an ARRIVE checklist did not lead to full compliance with the guidelines in the manuscript (Hair et al., 2018). Thus, legal enforcement of compliance with preparation and reporting checklists, in addition to comprehensive training on all checklist items, appears critical to fulfill already existing legal requirements as well as responsibilities to the public, which ultimately funds research and, as opinion polls (e.g., Clemence and Leaman, 2016) show, expects that suffering will be minimized.
